Teething, teething pain and teething remedies

Annetta K.L. Tsang

Abstract
Teething has long been regarded as an unpleasant experience for infants and their parents. Many parents, child carers and health professionals still believe that teething signs and symptoms and in particular, teething pain, should be managed. There is limited evidence to support current pharmacological and non-pharmacological therapies for teething, and the risks associated with some current agents may outweigh their supposed benefits. This paper discusses the current understanding of teething, teething pain and the management of teething in infants.

Keywords: Teething, primary tooth eruption, infant, pain, teething symptoms, teething remedies.

Introduction
Even though teething is a normal part of infant development, surprisingly little is known about the causes and management of teething signs and symptoms. It is widely believed that pain and other discomfort associated with tooth eruption in infants should and can be managed by pharmacological and non-pharmacological means, but this has yet to be proven. This paper presents the current understanding of teething, teething pain and the management of teething pain, based on current literature.

Teething
The eruption of primary teeth usually begins around 4-8 months of age with the eruption of the lower incisors, and is complete at around 30-36 months of age when second primary molars erupt. The timing of tooth eruption varies by as much as six months. The physiological process of tooth eruption is regulated by an array of genes, hormones and factors (Table 1).

Teeth eruption requires bone resorption and formation on opposite sides of the dental follicle to create an eruption pathway. The tooth germ forms within a dental follicle covered by the reduced enamel epithelium, which fuse to the oral epithelium over the cusp of the developing tooth. Prior to the tooth crown emerging through the gingiva, the overlying epithelium degenerates. The periodontal ligament and the ongoing development of the pulp and roots tooth provide the motive forces for eruption.

Teething Disturbances
Neanderland described three common perceptions of teething: i) teething is pathological and has cause-effect
relationships with symptoms, ii) teething is physiological, symptoms are merely co-incidental; and iii) teething is predominantly physiological, and discomfort is a normal consequence. For many people, teething is perceived to cause significant discomfort to infants and substantial distress to the parents (Table 2).\(^1\,1^2,1^3-3^0\) Disturbances are transient but may recur repeatedly during 4 to 36 months of age. Evidence regarding teething signs and symptoms is mostly subjective comments from parents, child care workers and/or health professionals.\(^2\,1^0,1^4-1^7,2^1,2^6-3^2\) Moreover, studies of teething have in general been small, retrospective, descriptive and cross-sectional in design.

Studies of larger cohorts\(^1^3\) show no causal association between teething and infection, fever, or diarrhoea. In some children, teething may be associated with increased drooling, sucking of digits and rubbing of gingivae. Nevertheless, more recent prospective studies reveal that most systemic teething signs and symptoms (fever, vomiting, facial rashes, sleep disturbances, stool looseness, decreased appetite for liquids, and cough) are due to other causes.\(^1^,1^6-1^9,2^2,2^4,3^2\) Examples of these alternate causes are well documented in the literature,\(^2^7,3^3-3^8\) and include meningitis, bacterial infections, and herpes simplex virus infections. The latter are painful in their own right.\(^3^4-3^7\) Teething disturbances may also be due in part to development changes, including the decline of maternal antibodies,\(^1^0,2^4,3^9,4^0\) while wakefulness and night crying may be due to separation anxiety or attention seeking.

Teething Pain

Teething pain, sometimes referred to as “dentitio difficilis”, is the commonest symptom associated with the eruption of the primary dentition.\textsuperscript{4,10,23-25} Despite a reported prevalence of around 85\%, evidence for this condition is weak.\textsuperscript{4,10,23-25,41} Adults assume an infant is experiencing pain because they appear distressed, or because they believe the incisal edges of teeth “cut through” the alveolar bone and gingiva during eruption.\textsuperscript{24,40,41} Pain may result from elevation of inflammatory mediators in the crevicular fluid and in tissues surrounding the erupting tooth, which stimulate nociceptive receptors.\textsuperscript{3-6,8,10,24,43-45} Local pain may be further exacerbated by rubbing or scratching the gingival tissues, by biting into hard objects, or by the presence of pathology such as eruption cysts.\textsuperscript{10,45,46}

Management of Teething Pain

There is no basis for the aggressive management of teething symptoms.\textsuperscript{4,10,24,47} Historical practices with no sound basis are many, and include lancing the overlying gingival tissues, applying leeches,\textsuperscript{24} applying necklaces,\textsuperscript{10,48} rubbing the gingiva with various animal extracts, and administering or applying heavy metal salts or opiates.\textsuperscript{10,18,24}

The management of teething pain is still the most frequently sought teething advice today.\textsuperscript{4,11,31} Despite a lack of evidence supporting the efficacy of teething remedies, parents and health professionals have continued to actively manage teething.\textsuperscript{10,41,49,50} Many teething remedies are implemented without the advice of a dental professional, but rather based on input from community nurses, friends, other mothers, self-help books, doctors and pharmacists. Pharmacological and non-pharmacological strategies are usually used in combination.

<tr>
<td>Rubbing</td>
<td>Gingival massage using firm finger pressure</td>
</tr>
<tr>
<td></td>
<td>Chewing of teething rusks, dry toasts, pacifiers</td>
</tr>
</tbody>
</table>

Non-pharmacological strategies

These approaches aim either at cooling the teething site and/or rubbing the site (Table 3).\textsuperscript{\textsuperscript{10,24,31,51}} Cooling may reduce inflammation by causing constriction of dilated blood vessels and by temporarily numbing the gingivae.\textsuperscript{52} In contrast, pressure from chewing and gingival massage may reduce pain by overwhelming the sensory receptors.\textsuperscript{31,51}

Pharmacological strategies

Pharmacological strategies for teething generally aim to achieve analgesia, anaesthesia, sedation or a combination of these (Table 4).\textsuperscript{10,24,31,51,52,55-71} While a range of preparations are available over the counter, evidence for efficacy against teething pain has yet to be demonstrated.\textsuperscript{53}

Paracetamol

Paracetamol (Table 4), also known as acetaminophen, is used commonly in managing teething pain and other symptoms. It reduces synthesis of prostaglandins by inhibiting cyclooxygenase-3 in the central nervous system.\textsuperscript{54,56,72,73} Analgesia results from the peripheral blockade of nociceptive impulses and their generation. Antipyresis results from the central inhibition of the hypothalamic heat-regulatory centre. In addition, paracetamol reduces hyperalgesia by reducing production of Substance P and nitric oxide.\textsuperscript{73}

Overdosing with paracetamol results in hepatocellular necrosis, renal tubular necrosis and death.\textsuperscript{24} For infants, paracetamol is commonly used at a dose of 10-15mg/kg/dose every 6-8 hours. At the lower end of this recommended dosage, paracetamol lowers fever but has little effect on pain.\textsuperscript{74,75} Analgesic effects require a dose of at least 15mg/kg.\textsuperscript{76}
Paracetamol may be formulated alone or in combination with other agents (Table 4). A particular concern is drug interactions when additional agents are used, such as herbal remedies, or preparations which contain high concentrations of ethanol.78,79

**Ibuprofen**

Ibuprofen is a commonly used non-steroidal anti-inflammatory drug (NSAID) in children. It exerts analgesic, antipyretic and anti-inflammatory effects,75,76,80,81 through peripheral inhibition of cyclooxygenases and prostaglandin synthetase. Compared to paracetamol, ibuprofen may be more efficacious for management of pain and fever though it causes more frequent adverse reactions in children.80,81

**Choline Salicylates**

Salicylates are synthetic NSAIDs with analgesic, antipyretic and anti-inflammatory actions. Choline salicylate is a “counter-irritant”,23,55-57 which when applied topically irritates sensory nerve endings and causes vasodilatation, which alters pain in the underlying tissues served by the same nerves.55-57

Used sparingly, choline salicylate does not cause mucosal irritation, however excessive application can cause a chemical burn.24,57 Being related to aspirin, choline salicylate may cause Reyes syndrome in susceptible children, especially those with or recovering from viral infections, or when used in combination with other NSAIDs.31,40,58

**Lignocaine and Benzocaine**

These local anaesthetics agents are found commonly in teething preparations (Table 4).58 Both act by decreasing the permeability of sodium ion channels in neuronal membranes leading to inhibition of depolarization and inhibition of nerve impulse propagation and conduction.59 There are no studies on the efficacy of these topical anaesthetic agents for teething, however supportive literature exists for temporarily relief of toothache60,61 and for relief of pain associated with needle penetration into mucosal tissues.62-65

As an amino-acyl amide, Lignocaine (or Lidocaine) penetrates oral mucosa readily.59,63 Temporary pain relief is possible using 5% lignocaine gel.63 The mucosal onset of anaesthesia occurs within 2-5 minutes, with a duration of 10-20 minutes.58,63 Blood levels after topical application of lignocaine is similar to that of intravenous administration.65 Side effects from this agent are rare when used in accordance with recommendations.59

In contrast, benzocaine is an ester anaesthetic agent.59 It also penetrates the oral mucosa well,60,64,65 with an onset and duration of action similar to lignocaine.59,63 Benzocaine at a concentration of 20% gives temporary relief of pain on mucosal tissues.59,60,63-65 However, as an ester, it poses a higher risks of hypersensitivity reactions and severe adverse effects such as methaemaglobinaemia.58,66-70

**Complementary and Alternative Medicines**

A range of complementary and alternative medicines (CAM) have been suggested for managing teething pain, including tea tree oil-basedointments, clove oil-based ointment, acupressure, herbal formulations, aromatherapy and homeopathic remedies.24,82 None of these methods has proven effectiveness for managing teething pain.24,82 Problems may arise when CAM are used in conjunction with conventional analgesics, for example, garlic interferes with the pharmacokinetics of paracetamol.79,83

**Discussion**

Eruption of primary teeth is a significant developmental milestone for infants. As highlighted in the foregoing discussion, there is only weak evidence for pain and no evidence to support the wide array of systemic signs and symptoms often attributed to teething by parents, child carers and health care professionals. Bennett and Brudno50 in the Pediatric Infectious Disease journal presented a deliberately flawed study on teething. Their paper “The teething virus”50 highlighted the lack of evidence-based practice in the management of teething symptoms. Teeth, whether primary or permanent, do not “cut” through bone, connective tissue and oral epithelium during eruption as an eruption pathway is formed by bone remodelling. The lack of any significant “teething pain” associated with eruption of permanent teeth is remarkable. Although it can be argued that in older children there is greater pain tolerance and lower pain sensitivity compared to infants.84,87

If some pain is experienced during teething, this will be impossible to assess reliably because infants cannot communicate their pain specifically or describe their pain experience explicitly. Instead, adults interpret various cues (vocalization, facial expression, body movements and changes in breathing rates) and attribute these to pain in the infant.84,85 Such cues are not specific and are caused by other forms of stress or distress. Moreover due to cortical immaturity of infants, biologic responses to stimuli are not consistent.85

"Indicated for oral treatment of pruritus irrespective of the cause”
"Not recommended for children under 2 years old” |
Despite uncertainty surrounding teething pain per se, most prefer to manage teething actively using a combination of non-pharmacological and pharmacological means. Given that evidence supporting the presence of teething pain is inconclusive and the efficacy of most current therapies against teething pain is yet to be determined, the risks vs. benefits of using various therapies must be considered with great care. The placebo effect must not be overlooked. For example, applying a gel of 20% benzocaine in polyethylene glycol may give only a modest benefit over applying the placebo, which gives an efficacy of 60% compared with 90% for the active preparation. Moreover, the efficacy of such topical applications is limited by dilution of the active components into saliva. The limited benefit of using topical gels for the duration of teething (24-36 months approximately) is further argument against such practices.

Overall, the risks and adverse effects from inappropriate or prolonged use of pharmacological agents outweigh their potential benefits. The psychological trauma involved in administering medications or applying topical preparations to infants must be considered. Attributing symptoms and signs to teething, without first excluding other causes, may result in misdiagnosis and delayed management of more serious systemic conditions which cause fever and other systemic signs. Cognitive management of teething should be considered. Behavioural therapies such as sleep management can be used to combat sleep disturbances, wakefulness and irritation.

This paper highlights the importance of separating time-honoured myths and traditions from evidence-based practices. Parents, carers and health professionals need to be well informed and given rational rather than conflicting advice. To that end, further research into teething and its management should be supported and encouraged. Likewise, the inclusion of teething and its management as a topic in antenatal classes, in professional health programs and in continuing professional education for health professionals and childcare workers should be considered.
